ARTICLE INFO

Abstract

Introductions: Azithromycin is the most popular prescribed antimicrobial agent around the world. It comes under the class of macrolide antibiotics. Because of its higher efficacy, tolerance, and broad-spectrum activity, it is primarily used in upper and lower respiratory tract infections, some sexually transmitted infections, and major bacterial infections.

Methods: Pieces of literature were reviewed to access the risk and benefits associated with azithromycin.

Results: Generally, this is commercially available in solids, liquids, and ophthalmic formulations due to its minimal adverse events. It is also used in the case of COVID-19 drug therapy due to its pharmacological and therapeutic properties.

Conclusions: The review of literature presented that it may increase the risk of cardiac death, hepatic injury, ototoxicity, hypersensitivity reactions.
the serum of enzyme and liver biopsy found in ductopenia. Azithromycin induces the absence of the bile duct in other patients and produces serious ductopenia which biliary cirrhosis which eventually needs liver transplantation due to liver dysfunction (Martinez et al., 2015).

The risk associated with cardiovascular System

It was reported, that there is an increase in the Q-T prolongation in elderly patients by taking azithromycin (Russo et al., 2006). So, the evidence suggested that azithromycin may have an initial stage of cardiac arrhythmia related adverse effects including polymorphic ventricular tachycardia with the absence of Q-T intervals (Kim et al., 2005)torsades de pointers(Huang et al., 2007) and various studies showed that azithromycin increases risks of cardiovascular death. In the years 2012 and 2013 the study found that an increase in the risk of cardiac death by taking azithromycin is similar to amoxicillin (hazard ratio, 2.49-95% CI,1.38 to 4.50; P=0.002) followed by Tennesse Medicaid cohort design (Ray et al., 2012). A cohort study with 1.1million Danish adults with azithromycin showed that no cardiac death risk as compared with penicillin V(rate ratio,2.85-95%CI,1.13 to 7.24)(Svanstrom et al., 2013). The FDA also concludes the adverse event of azithromycin use, it can potentially cause irregular heart rhythms, QRS complex, torsades de pointes (Poluzzi et al., 2009).

The risk associated with blood circulatory System

Azithromycin is preferred as the first-choice drug in bacterial infections as compared to other antibiotics because of their better bioavailability and lower side effects but in a clinical trial study in Japan it was observed that 11 patient showed leukopenia (0.88%), 2 patients showed neutropenia (0.22%) after taking azithromycin therapy (Higa & Saito, 2000). These adverse events are reported too mild and transient especially abnormal neutrophil count is observed in adults is 1.5% and more in children (1.9%) (Treadway & Pontani, 1996).

The risk associated with topical use

No case of adverse event was reported due to the topical use of azithromycin earlier to the year 2011 (Flavia Monteagudo Paz et al., 2011). The first case was reported in 2011 of an 85-year-old lady with a history of bilateral phacoemulsification, allergic rhinoconjunctivitis, and chronic dacrocystitis. After a 1-year interval, the second time application of Ayzyer eye drop causes an adverse event. Then when she stopped Ayzyer, on the next second-week eyelid eczema was improved.

Department of Dermatology, Hospital General Universitario de Alicante also found an adverse event of Azithromycin. A 76-year-old lady, who had to have acute eczema and acute conjunctivitis affecting the eyelids and cheeks, was reported. Three months before the event, she underwent pseudophakia surgery. Due to that, she prescribed tabradex and azydrop single-dose container. As it was suspected that allergic contact dermatitis was caused by this two ophthalmic preparation the application of these eye drops was stopped. Then after two weeks, later the patient had improved (Milovic-Kraus & Kanceljak-Macan, 2001).

Occupational allergic contact is generally common and was observed in the case of pharmaceutical workers who were involved in azithromycin synthesis or formulation. This shows air-bone contact dermatitis. The Spanish baseline series patch testing D2 and D4 showed a positive reaction to azydrop. But this was the first case of non-occupational allergic contact dermatitis reported ever but no positive reactions were observed by erythromycin and clarithromycin so it could be possibly be explained. Erythromycin and clarithromycin containing 14 carbon atoms but azithromycin contain 15 carbon atom cycles (Milovic-Kraus et al., 2007).

The risk associated with the auditory system

Azithromycin rarely causes ototoxicity (Wallace et al., 1994; Tseng et al., 1997). Most of the people had a problem with reversible SNHL during prolonged high-dose therapy related to AIDS. But a rare case of irreversible SNHL was found in a 39-year-old woman when exposing to low dose azithromycin. Who just started taking azithromycin for urinary tract infection. She was advised to take two tablets of 250 mg per day but she stopped after the second dose due to worsening tinnitus and subjective bilateral hearing loss. She did not have any past medical and family histories. She also denied vertigo, imbalance, or other vestibular symptoms. But Still auditory symptoms did not improve after she stopped the medication. Azithromycin comes under macrolide antibiotics. Which causes Macrolide ototoxicity from the early 1970s (Mintz et al., 1973).

The risk associated with GIT

Most of the antimicrobial agents having the major risk factor of clostridium difficult infections (CDI). In some articles, it was found that the risk of CDI infection was different with different classes of antibiotics followed by the meta-analysis method. Macrolide antibiotics are a lesser risk of CDI as compared to clindamycin and fluoroquinolones antibiotics. Azithromycin is coming under macrolide antibiotics so that the risk of clostridium difficult infections is low (Deshpande et al., 2013; Brown et al., 2013).

Risk of drug-interaction

Azithromycin is a macrolide class of antibiotics it contains bacteriostatic effects of both gram +ve and gram -ve microorganisms (McMullan & Mostaghim, 2015). The Macrolide class of antibiotics also affects the other drugs of the metabolism process. Except Azithromycin and clarithromycin do not significantly interfere with the metabolism process. Many of the drugs are metabolized by microsomal isoenzyme CYP3A4. This macrolide class of drugs interacts with other drugs and it inhibited the CYP450
so it prevents the activation of other enzymes responsible for metabolism it can lead to increases in the drug concentration and produce toxic effects (Franklin, 1977). Various compounds are available over the counter (OTC) so, physicians are generally aware of this type of interaction and cautious for antibiotics prescribing.

**Use of azithromycin in combination with theophylline**

It is widely used in bronchodilation for the treatment of asthma patients. These drugs are generally metabolized in isoenzyme CYP3A4 in the liver. Coadministration of other drugs in the same pathway can competitively inhibit the Theophylline clearance. The macrolide class of Erythromycin and Theophyllin are also be metabolized in the CYP450 enzyme (Ludden, 1985). So Theophylline metabolism inhibited and increases the plasma concentration and produced toxic symptoms include dizziness, headache, tachycardia, palpitation, etc. Some studies suggest that the combination of Azithromycin and Theophylline no significant increases the plasma concentration of Theophylline. Azithromycin contains a lack of effect on CYP450 interaction. As a result, these studies suggest that Azithromycin can administer Theophylline use of asthmatic patients (Debruyne et al., 1986).

**Use of azithromycin in combination with cyclosporine**

Cyclosporine is an immunosuppressant drug commonly used in graft rejection of organ transplantation and also used in an autoimmune disorder. This cyclosporin is also metabolized in liver isoenzyme CYP3A4. Antibiotics like macrolide class also are metabolized in this isoenzyme so cyclosporine not metabolized it and increases the cyclosporine concentration (Kronbach et al., 1988). Increases plasma concentration causes renal dysfunction, hepatotoxicity, abdominal pain, psychosis, etc (Jensen et al., 1987). In a study 3995 patients administer Azithromycin, no case has been found in Azithromycin-Cyclosporine interaction (Vernillet et al., 1989). As a result of no interaction occurs between Azithromycin-Cyclosporine.

**Use of azithromycin in combination with carbamazepine**

Carbamazepine is an anticonvulsant drug used to treat patients with epilepsy. These drugs also interact with antibiotics. To suggest the physician appropriately choose the medication and prescribe it. Signs of toxicity include confusion, vertigo, ataxia, and vomiting, etc (Nahata, 1996). In the case of Azithromycin are not able to find any interaction with Carbamazepine (Rapeport et al., 1991). In clinical studies more than 600 patients receive a combination of medication, to find no clinical evidence combination with Azithromycin (Hopkins & S, 1994).

**Use of azithromycin in combination with warfarin**

Warfarin is generally used in anticoagulant to prevent the clotting factors. Erythromycin also inhibits Warfarin metabolism as a result increases the serum concentration to causes an increase in prothrombin time and hemorrhage (Bartle, 1980). A case of 23 healthy volunteers in the combination of Azithromycin and Warfarin to show an absence of interaction between them. As a result, Azithromycin is not to be affected in prothrombin time while administrating the warfarin (Sato et al., 1984).

**Use of azithromycin in combination with hormonal contraceptives**

This contraceptive pill available in either progesterone-estrogen combination or only progesterone preparation. It is also effective for birth control. These contraceptive pills are also an interaction between broad-spectrum antibiotics (Orme et al., 1991). In a clinical review of 6655 patients, not any interaction between azithromycin and Oral contraceptive (Nahata, 1996).

**Use of azithromycin in combination with zidovudine**

Zidovudine is widely used in AIDS treatment to inhibit the reverse transcriptase enzyme. In a study, azithromycin also administers HIV patients not able to affect zidovudine metabolism. As a result, azithromycin also is used in HIV-affected patients used in zidovudine (Chave et al., 1992).

**Use of azithromycin in combination with Antacaid**

Antacids are generally used to neutralize the acid in the stomach and are used in the treatment of gastritis, Zollinger Ellison syndrome, and ulcer. In the case of Azithromycin administer with Antacaid to decreases the absorption of Azithromycin concentration in the body. To avoid this type of interaction to take after 3hr. administration of Azithromycin. Physicians provide information about the interaction between those drugs (Foulds et al., 1991).

**Use of azithromycin in combination with hydroxychloroquine**

HCQ is a popular drug widely used in the treatment of Malaria, Rheumatoid arthritis, currently used in Coronavirus infections. Together with use in HCQ and Azithromycin to causes increases the risk of irregular heart rhythm and QT prolongations. This type of interaction has harmful effects on our body system. Clinicians are finding out the history of any heart risk of patients and to avoid this type of combination.

**Risk in SARS Cov-2**

COVID-19 or SARS Cov-2 is known as a severe acute respiratory syndrome. There are four types of coronavirus such as alpha, beta, gamma, and delta. The genomic structure of the Coronavirus is a single standard RNA virus (+SSRNA) and the diameter is 80-120 nm. The mechanism of the Coronavirus is bound to the ACE2 receptor of the human lungs. Various types of medicinal agents are used to treatment of Coronavirus such as hydroxychloroquine,
azithromycin, favipiravir, and remdesivir, etc (Wrapp et al., 2020).

Azithromycin is widely used for COVID-19 treatment. It is a macrolide class of antibiotics derived from erythromycin. This drug is highly potent and increases the penetration of tissue and it inhibits the 50s ribosomal subunit to halt the protein synthesis (Parra-Lara et al., 2020). Fatal cardiac arrhythmias are caused by azithromycin in coronavirus treatment. Azithromycin may also be induced QTc prolonged and increased torsed de points (Tdp) (Kezerashvili et al., 2007) studied that, a 55-year-old patient to show the QT extension and Tdp associated use in Azithromycin. Observed that, a 90-year-old man with high blood pressure after taking Azithromycin within few hours to increase QT extension and Tdp. The Macrolide class of Azithromycin also inhibited CYP3A4 metabolism so increases the risk of Tdp (Guo et al., 2010). Those patients are associated with a high-risk cardiovascular disease it increases the chance of death of the patients. In some case reports studies observe that middle-aged adult patients are not associated with cardiac death but some age patients between 60–70 age patients are at high risk of cardiovascular diseases (Hancox et al., 2013). Azithromycin-related adverse effects mainly nausea, vomiting, abdominal pain, and diarrhea are seen in only 10% of cases. The mechanism of EAD and QT interval is prolonging due to blocking the efflux of potassium ions. The combination of HCQ and Azithromycin causes increases in the risk of mortality rate. Alone HCQ uses to decrease the mortality rate. Among those patients having a high risk of coronary artery disease to take azithromycin to increases cardiac death (Lighter & Raabe, 2020). In the above studies, caution is if Azithromycin is used with Hydroxychloroquine or alone to treat Coronavirus both are risk of torsed de points (Sultana et al., 2020).

**Conclusions**

Safety and efficacy both are important factors. From the study of the above research articles, we conclude that no doubt azithromycin is a highly potent and well-tolerable oral antibiotic, most frequently prescribed by the physician but it may also show some adverse effects. So due safety point of view more this type of study should be done and a comparison test also should be done with other antibiotics to detect the problem.
